**Abstract**

This report describes a comparison study between the CUDD and BuDDy OBDD package. The performance of the two packages is evaluated on three sets of AI planning problems from the AIPS-98 and AIPS-00 planning competition. Our experiments indicate that CUDD has a slight implementation overhead compared to BuDDy. However, for some problems this overhead is overcome by the fact that CUDD can perform negation in constant time.

This work was supported in part by the Danish Research Agency and the United States Air Force under Grants Nos F30602-00-2-0549 and F30602-98-2-0135. **Keywords:** OBDD manipulation, AI planning

# 1 Introduction

Currently, no comparison studies exist between the CUDD and BuDDy OBDD package [7, 4]. The object of the experiments described in this report is to provide such a study for a particular class of problems. The problems considered are classical AI planning problems. A planning problem is a graph search problem. Vertices of the graph denote world states and edges denote deterministic state transitions. The input to a planning problem is the search graph, an initial state, and a set of goal states. The output is a path leading from the initial state to one of the goal states.

OBDDs [2] are applied in the usual way to perform symbolic search [6]. Thus, in each iteration of a forward (backward) search algorithm, all next states (previous states) are computed via the image (preimage) computation. In this study, we apply forward and backward search for three planning problems: Gripper (AIPS-98), Logistics (AIPS-00 round 1), and Blocks (AIPS-00 round 1) [5, 1]. Our implementation uses standard techniques to reduce the complexity of the OBDD operations. In particular, we partition the transition relation into a disjunctive partitioning according to an upper bound of the OBDD size of each partition. This lowers the complexity of computing the transition relation and performing image and preimage computations. In addition, we apply frontier set simplification. However, in this study, Coudert, Berthet, and Madre’s minimization technique [3] of the frontier set has not been applied.

Figure 1: (a) CUDD representation. (b) BuDDy representation.

The initial cache size and the initial number of allocated slots in the unique table of the OBDD packages have been hand-tuned for best performance in each experiment. We also adjusted the upper bound of the size of the OBDDs in the disjunctive partitioning for best performance. All experiments were carried out on a Linux Redhat 7.1 PC with a 500 MHz Pentium III CPU, 512 KB L2 cache and 512 MB RAM. The time limit (TIME) was 300 seconds and the memory limit (MEM) was 300 MB.

The most significant difference between the CUDD and BuDDy package is that only CUDD applies complemented edges. A key result of the comparison experiment is therefore to determine to what extent CUDD can benefit from this representation when applied to planning problems. Our experiments indicates that CUDD has a slight implementation overhead compared to BuDDy. However, for some problems this overhead is overcome by

the fact that negation can be done in constant time.

## 2 Experiments

For each problem, we perform experiments for forward and backward search. We conduct a timing study that measures the total CPU time  $T$ , the time used to produce the transition relation  $T_r$ , the search time  $T_s$ , the solution extraction time  $T_e$ , and the average size of the OBDDs representing the search frontier  $|f|$ . All time measures are in seconds.

It should be noted that CUDD and BuDDy measure the size of an OBDD slightly different. For BuDDy, the size equals the number of internal nodes of the OBDD, while it for CUDD equals the sum of the number of internal and terminal nodes of the OBDD. Figure 1 shows the CUDD and BuDDy representation of an identical Boolean function. The CUDD size is 4, while it for BuDDy is 5.

## 2.1 Gripper

This problem scales well when using an OBDD approach. Solution paths are long, but the frontier OBDDs only grow moderately. The results are shown in Table 1 and Table 2.

## 2.2 Logistics

The logistics domain is hard for OBDD-based blind search due to a high growth rate of frontier OBDDs. The results are shown in Table 3 and Table 4.

$p$	CUDD					BuDDy

	$T$	$T_r$	$T_s$	$T_e$	$ f $	$T$	$T_r$	$T_s$	$T_e$	$ f $
4	0.36	0.09	0.14	0.03	300	0.42	0.09	0.19	0.02	300
5	0.55	0.09	0.33	0.03	571	1.11	0.09	0.45	0.03	571
6	0.75	0.09	0.49	0.03	1314	1.18	0.09	0.55	0.02	1315
7	179.39	0.39	177.28	0.15	46906	272.20	0.35	267.93	0.06	46906
8	TIME					TIME				

Table 4: Logistics results for backward search.

## 2.3 Blocks

Similar to the Logistics domain, frontier OBDDs in the Blocks domain tend to grow fast. The results are shown in Table 5 and Table 6.

## 3 Conclusion

The most striking result of these experiments is that the size of the OBDDs with complemented edges used by CUDD is almost identical with the size of the ordinary OBDDs used

Table 6: Blocks results for backward search.

by BuDDy<sup>1</sup>. However, complemented edges makes it possible for CUDD to perform negation in constant time. For search problems, an efficient negation operation may improve the complexity of pruning the search frontier from previously reached states, since a potentially large OBDD representing the previously reached states must be negated and conjoined with the OBDD representing the frontier. This seems to be an advantage for some problems. For instance, in the Logistics domain, CUDD is about twice as fast as BuDDy on the harder problems.

However, in the Blocks domain, BuDDy is slightly faster than CUDD even for hard problems. Together with the results in the Gripper domain, this seems to indicate that CUDD is implemented with a slight overhead compared to BuDDy, but that efficient negation may overcome this overhead for certain problems.
